The Galactic center

Delphine Porquet

(CNRS, Observatoire Astronomique de Strasbourg, France)
Galactic Center: one of the most richest regions of the sky

* Distance ~ 8 kpc

* High column density along the line-of-sight: \( N_H \sim 5-7 \times 10^{22} \text{ cm}^{-3} \) \( (A_v \sim 25-30) \)

⇒ ‘only’ observable in radio, IR, X-rays \( \geq 1-2 \text{ keV} \) et γ-rays

* Extended objects:
SNR, molecular clouds, non-thermal, filaments, diffuse emission, ...

* Stars

* Compact objects:
X-ray binaries (neutron stars, black holes, white dwarfs), SMBH: Sgr A*, ...

A zoom on Sgr A*
I. Current view of Sgr A*
Sgr A*: SMBH at the Galactic center

- Closest supermassive black : D ~ 8 kpc
- Stellar orbits ⇒ $M_{\text{BH}} \sim 4 \times 10^6 \, M_\odot$
- Largest BH in projection
  ⇒ best place to test GR directly in a strong gravitational field.

- First detected as a non-thermal radio source with a proper motion of $-0.4 \pm 0.9 \, \text{km/s}$
- Size @ 1.3mm : 37 (+16,-10) $\mu$arc i.e., 0.3 A.U. or 4 $R_S$
- Bolometric luminosity: $L_{\text{bol}} \sim 10^{36} \, \text{erg.s}^{-1} \sim \times 100 \, L_\odot$
  $10^{-8}-10^{-9} \times L_{\text{Edd}} \quad (\equiv 1.26 \times 10^{38} \, M/M_\odot \sim 4-5 \times 10^{44} \, \text{erg/s})$

- Faintness certainly due to a combination of :
  - A relatively low accretion rate at the Bondi radius ($\sim 4'' = 4 \times 10^5 \, R_S$) : $\dot{M} \sim 10^{-5-6} \, \dot{M}/\text{yr}$
  - Inefficient angular-momentum transport
  - Outflows,
  - Low radiation efficiency ($\eta \sim 10^{-6}$)

- Rotation measure (position angle of the linear polarization vector at $\neq$ wavelengths):
  $< 2 \times 10^{-9} - 2 \times 10^{-7} \, \dot{M}/\text{yr}$
  (depending of the B configuration in the accretion flow)

Keck/UCLA GC group

Spectral energy distribution of Sgr A* (steady/quiescent state)

- **Radio**: predominantly optically thick synchrotron radiation from thermal electrons ($kT \sim 10\text{--}30 \text{ MeV}$) \( T_e \sim \text{a few } 10^{10} \text{K}, \ n_e \sim 10^6 \text{ cm}^{-3}, \text{ and } B \sim 10\text{--}50 \text{ G} \)

- **X-rays**: FWHM = 1.4" (1" = 10\text{^5} R_s = 0.04 \text{ pc}) similar to the size of the Bondi accretion radius. Probable origin: thermal bremsstrahlung from the transition region between the ambient medium and the accretion flow.

Less clear whether there is a steady NIR counterpart. And no detection in MIR yet.

Models for the quiescent emission: ADAF, RIAF, CDAF, ADIOS, jet, jet/ADAF, ....
Sgr A* : a “quiescent” SMBH ... but not inactive

- Bolometric luminosity: $L_{\text{bol}} \sim 10^{36}\ \text{erg.s}^{-1} \sim 100\ \text{L}_\odot$! $\ll$ AGN ($\geq 10^{42}\ \text{erg.s}^{-1}$)
  10^{-8}-10^{-9} times weaker than the Eddington luminosity
  $\Rightarrow$ Extremely low radiative efficiency and low accretion rate.

  $\Rightarrow$ Daily flares: $\sim 1$ every day in X-rays and up to several per day in NIR
  $\Rightarrow$ New perspectives for the understanding of the processes at work in “quiescent” supermassive black holes.

Chandra (Baganoff et al. 2001)

Keck II 10 m: adaptive optics L’ (3.8 μm)
Ghez et al. (2004)
Most X-ray flares are weak (≤10) or moderate (≤40) BUT two (first) brightest X-ray flares from Sgr A* has been observed with XMM-Newton.

- **2007, April 4**: Porquet et al. (2008)

- **duration ~ 3000 s**
- **amplitude at the peak: ~ 160 and 100**
  \((\sim x 3.5 - 2.2 \text{ October 2000, Chandra})\)

\[ L_{2-10\text{keV (peak)}} = 3.6-2.2 \times 10^{35} \text{ erg.s}^{-1} \approx L_{\text{bol (quiescent state)}} \]

- **shortest time-scale: 200 s** \((3\sigma) \rightarrow 7 R_s\) \((R_s \sim 1 \times 10^{12} \text{ cm})\): very small region!
- **Bright to very bright X-ray flares have well constrained soft X-ray spectra** \(\Gamma \sim 2.2-2.3 \ (\pm 0.3)\) Not constrained for weaker flares!
The most energetic Sgr A* flare observed by Chandra/HETG

3 Msec (~35 days) of observations over the course of Chandra/HETG Cycle 13 (02/2012 - 10/2012) PI: F. Baganoff (MIT)

Aim: Observation and study of Sgr A*, and its surrounding inner few arcminutes
⇒ First high-resolution angular and high-resolution spectrum of Sgr A* during its quiescent state (ADAF/ RIAF, ...) and its flaring state.

Nowak et al. (2012):
A very bright flare (x 160) has been observed for the first time with Chandra in Feb. 2012 ⇒ Oct 2002 XMM-Newton flare but twice larger in time.

⇒ Consistent with the “soft” spectral shapes found for the 2 brightest XMM-Newton X-ray flares (Porquet et al. 2003, 2008)
See Dominic Walton’s talk about NuSTAR (Thursday)
Multi-wavelength overview of SgrA* flares
NIR/X-ray Flares

When simultaneous X-ray and NIR observations:

All X-ray flares have NIR counterpart BUT not all NIR flares have (detected) X-ray counterpart

First observations of a flare detected at X-ray, NIR and sub-mm

Marrone et al. (2008)

* $L_{\text{peak}}$ (2-8keV) $\sim 40 \times 10^{33}$ erg/s

Amplitude $\sim x$ 20

* NIR data begins 36 min after X-ray peak

* Sub-mm flare occurs nearly 100 min after the X-ray peak.
X-ray hiccups from SgrA* on April 4th 2007
Porquet et al. (2008)

4 flares detected within 12 hours with different amplitudes!

Detection of the second brightest X-ray flare from SgrA*: ~x 100

followed by 3 moderate X-ray flares: ~ x 25-40

Simultaneous multi-wavelength observation campaign: from radio to X-rays
Brightest IR/X-ray flare (April 4th 2007)
(Porquet et al. 2008; Dodds-Eden et al. 2008)

Possible emission mechanisms for the X-ray flares:

**Synchrotron scenario:**
- X-rays (as for NIR)

**Synchrotron self-Compton (SSC):**
- NIR photons are up-scattered by the same e\(^-\) responsible for the NIR synchrotron radiation.

**Inverse Compton Scattering:**
- Sub-mm photons (quiescent) are up-scattered by the NIR e\(^-\) (synchrotron)

**Observational constraints:**
- \( v L_v \propto v^{-\beta} \) with \( \beta_{\text{NIR}} > 0 \) and \( \beta_{\text{X}} = -0.3 \)
- NIR/X: simultaneous with 3 min
- Durations: FWHM\(_{\text{IR}}\) = 66 min, FWHM\(_{\text{X}}\) = 28 min
- IR shortest time-scale = 1.2 Rs in size
- Upper limit in MIR.
Hypothesis:

NIR: synchrotron emission
1) Sub-mm IC and SSC:
   Thermal distribution of transiently heated/accelerated electrons: $\gamma$ typical energy of the electron distribution $kT_e/mc^2$
   2) Synchrotron with a cooling break:
      Power law energy distribution of accelerated electron $N(\gamma) \propto \gamma^{(3-p)/2}$ (below cooling break) $\propto \gamma^{(2-p)/2}$

Sub-mm IC: $\gamma \leq 1000$, $B \geq 25$ G, and $R$ (sub-mm seed photons) $< 0.1$ Rs $\ll R$ (VLBI)

SSC: $\gamma \leq 100$, $B \geq 2400$ G, and $R$ (seed IR photons) $< 0.002$ Rs $\rightarrow n_e > 10^{10}$ cm$^{-3}$ $\gg \sim 1000$ $n_e$ and $B$ in the inner accretion flow (Yuan et al. 2003)

Synchrotron with a cooling break:
   $B \sim 6$ G and $p \sim 2.4$

$\Rightarrow$ Most viable scenario for the X-ray emission:
   synchrotron from an electron distribution with a cooling break.

However other and/or more sophisticated scenarios has been proposed for SSC (e.g., Sabha et al. 2010) and IC (e.g., Yusef-Zadeh et al. 2012) that could explain these NIR/X-ray flare properties.
• The emission mechanism(s) of the daily (present) X-ray flares not yet settled: SSC, IC, or synchrotron?

• Associated mechanism(s)?
Increase of the accretion rate, accretion instability,
Turbulent shocks
Tidal disruption (asteroids)
magnetic reconnection, hot spots,
Tilted black hole accretion disc
Jet acceleration
Blob of relativistic plasma,
...

Simultaneous multi-wavelength constraints are required, e.g.:
Intensity, durations, timing, spectral and polarization properties, ...

See Grisha Karssen’s talk about “Modelling the flares of Sgr A*”
II. X-ray archaeology: X-ray echo(s) from a past activity of Sgr A*?

Molecular clouds close to Sgr A*: ~ 15 pc

\[ \Rightarrow 2 \text{-} 3 \text{ year long outburst of a point source (either Sgr A* or an X-ray binary) with a luminosity of at least } 10^{37} \text{ ergs s}^{-1}. \]

If Sgr A* then outburst occurred 60 years ago (14 pc in projection)

\[ \Rightarrow \text{A single flare from Sgr A* (} \sim 1.5 \times 10^{39} \text{ erg s}^{-1} \text{) fading about 100 years ago.} \]
Molecular clouds close to Sgr A*: ~ 15 pc

Contributions of cosmic-rays and/or other X-ray transient sources

Example of the Arches cluster (Capelli et al. 2011a, 2011b) as a likely location of particle acceleration.

Dogiel et al. (2013): This FeK emission “can result from the bombardment of molecular gas by energetic ions, but probably not by accelerated electrons.”

Fastest variability yet reported for the GC region: $t \sim 2-3$ years $\Rightarrow$ most likely the result of its X-ray illumination by a nearby transient X-ray source.

$+$ the non-zero underlying level of the FeK line flux, suggests the possibility that both the reflection and CR bombardment processes may be working in tandem.
Contributions of cosmic-rays and/or other X-ray transient sources?

Capelli et al. (2012)

⇒ A long-term downwards trend punctuated by occasional counter-trend brightening episodes of at least 5 years duration.
Wide-Field Radio Image of the Galactic Center
\( \lambda = 90 \text{ cm} \)
(Kassim, LaRosa, Lazio, & Hyman 1999)

- Sgr A* (SMBH)
- Sgr B2 (molecular cloud)
- Sgr C (molecular cloud)

\( \sim 0.5^\circ \)
\( \sim 75 \text{ pc} \)
\( \sim 240 \text{ light years} \)
Molecular clouds farther from Sgr A* (~100s years ago)

Sgr B2

decay time: $8.2 \pm 1.7 \text{ yr}$

$\Rightarrow$ period of intense activity of Sgr A*$^*$ (L$\sim 1.5-5 \times 10^{39} \text{ erg s}^{-1}$) ended between 75 and 155 years ago.

Sgr A*$^*$ continuously active with sporadic flux variabilities of $L_X (1-3) \times 10^{39} \text{ erg s}^{-1}$ in the past 50 to 500 years.

$+ 2$ short-term flares of 5-10 years.

$\Rightarrow$ multiple flares superposed on a long-term high state.

Ryu et al. (2013)

Terrier et al. (2010)
The Fermi Bubbles

Well centered on longitude zero (close to latitude zero)

**Origin:**

- Past AGN jet activity (~1-3 Myr lasted for ~0.1-0.5 Myr with and accreted matter mass ~100 –10000 $M_\odot$)?
- Wind bubble: nuclear starburst in the GC in the last 10 Myr?
- Dark matter annihilations?

NASA’s Goddard Space Flight Center

Finkbeiner, Su et al.
III. Back to the Future:

A renew of Sgr A* activity?

The incoming G2 « cloud »
A gas cloud on its ways into SgrA*  

Gillessen et al. (2011)

G2: dusty ionized cloud with $v = 1700 \text{ km/s}$, $e=0.966$ coplanar with the clockwise stellar disk.

$M_{\text{cloud}} \sim 3 \, M_{\text{Earth}}, \ T_{\text{dust}} \sim 550 \, \text{K}, \ T_{\text{gas}} \sim 10^4 \, \text{K}, \ L \sim 5 \, L_{\text{sun}}$

Should reach its pericenter in late 2013 or early 2014 at only $\sim 2200 \, R_{\text{s}}$ ($\sim 2 \, \text{mas}$) << $R_{\text{bondi}}$

Extended event $\sim 1 \, \text{year}$

Gillessen et al. (2013):

- Ionized gas in the head is now stretched over more than 15,000 $R_{\text{s}}$ around the pericenter of the orbit, at $\approx 2000 \, R_{\text{s}} \approx 20$ light hours from the BH.

- The first parts of G2 have already passed pericenter

Schartmann et al. (2012)
An unprecedented amount of satellites and ground-based telescopes are monitoring the Galactic center to follow the course and impact of the G2 "cloud" on Sgr A* activity.

- On April 24th: Increase in the X-ray flux from the vicinity of Sgr A* by an order of magnitude above its quiescent level (Degenaar et al. 2013)

The enhanced emission persisted much longer than typical Sgr A* flare events, which only last tens of minutes to hours!

The awaited outburst from Sgr A*?

- On April 25, during a scheduled observation of Sgr A*, the Swift/BAT triggered on a short (~30 ms), hard X-ray burst at a position consistent with Sgr A* characteristics of this burst were consistent with Soft Gamma Repeater (SGR) bursts (Kennea et al. 2013a)

- On April 29 (Chandra): located at only ~3" (i.e. ~ 0.1pc) from SgrA* (Rea et al. 2013)

SGRs are members of a very small group of sources (26 known to date), which are suggested to be magnetars (slowly rotating neutron stars with extreme surface dipole magnetic fields of >10^{14} G)
A NuSTAR follow-up observation on April 26 found a ~3.76 s periodicity well within the range of magnetar periods (2–12 s). 
+ Spin down rate implies $B = 1.6 \times 10^{14} \text{ G}$. 

*(Mori et al. 2013)*

This period has been confirmed in radio: $\Rightarrow$ fourth magnetar detected in radio wavelengths *(Eatough et al. 2013)*.

---

*Note:* The dip at day 163/164 is an instrumental/analysis artifact *(M. Reynolds - 130625)*.
IV. Observational perspectives ... Just to cite a few toys!

Multi-wavelength synergies of planned and proposed facilities, e.g. SKA, VLBI/EHT, ALMA, SPICA, JWST, E-ELT, ATHENA+, CTA, ...

(Adapted from figure in Dodds-Eden et al. 2009)
